Abstract

The problem of predicting a sequence $x_1, x_2, \cdots$ generated by a discrete source with unknown statistics is considered. Each letter x_{t+1} is predicted using the information on the word $x_1 x_2 \cdots x_t$ only. This problem is of great importance for data compression, because of its use to estimate probability distributions for PPM algorithms and other adaptive codes. On the other hand, such prediction is a classical problem which has received much attention. Its history can be traced back to Laplace. We address the problem where the sequence is generated by an i.i.d. source with some large (or even infinite) alphabet. A method is presented for which the redundancy of the code goes to 0 even for infinite alphabet.

Keywords: *Data Compression, adaptive coding, prediction of random processes, Laplace problem of succession, Shannon entropy.*

1 Introduction

The problem of prediction can be traced back to Laplace [5, 23]. Presently, the problem of prediction is investigated by many researchers because of its practical applications and importance for probability theory, information theory, statistics and other theoretical sciences, see [1, 7, 10, 13, 22, 23].

Consider a source with unknown statistics which generates sequences $x_1x_2\cdots$ of letters from an alphabet $A = \{a_1, \cdots, a_n\}$. The underlying true distribution, which is unknown, is indicated by the letter p. Let the source generate a message $x_1 \ldots x_{t-1}x_t \ldots$, $x_i \in A$ for all i, and let $\nu^t(a)$ denote the count of letter a occurring in the word $x_1 \ldots x_{t-1}x_t$. After the first t letters $x_1, \ldots, x_{t-1}, x_t$ have been processed the following letter x_{t+1} needs to be predicted. By definition, the prediction is the set of non-negative numbers $p^*(a_1|x_1 \cdots x_t), \cdots, p^*(a_n|x_1 \cdots x_t)$ which are estimates of the unknown conditional probabilities $p(a_1|x_1 \cdots x_t), \cdots, p(a_n|x_1 \cdots x_t)$, i.e. of the probabilities $p(x_{t+1} = a_i|x_1 \cdots x_t)$; $i = 1, \cdots, n$.

Laplace suggested the following prediction $p^*_L(a|x_1 \cdots x_t) = (\nu^t(a)+1)/(t+|A|)$, where $|A|$ is the number of letters in the alphabet A, [5, 23]. (The problem which Laplace considered was to estimate the probability that the sun will rise tomorrow, given that it has risen every day since the creation. Using our terminology, we can say that Laplace estimated $p(r|rr\cdots r)$ and $p(\bar{r}|rr\cdots r)$, where $\{r, \bar{r}\}$ is the alphabet ("sun rises", "sun does not rise") and the length of $rr\cdots r$ is the number of days since the creation.)

We will estimate the precision of the prediction by the Kullback-Leibler divergence between the true distribution $p(.|x_1...x_t)$ and its estimation $p^*_\gamma(.|x_1...x_t)$, where γ denotes a prediction method.

In data compression the average divergence is called redundancy and plays a key rule. Let us comment on the relation to data compression in more detail. An encoder can construct a code with codelength $l^*(a|x_1 \cdots x_t) \approx -\log p^*(a|x_1 \cdots x_t)$ for any letter $a \in A$ (the approximation may be as accurate as you like, if the arithmetic code is used, see [16, 12]). An ideal encoder would base coding on the true distribution p and not on the prediction p^*. The difference in performance (the redundancy) measured by the average code length is given by

$$\sum_{a\in A} p(a|x_1 \cdots x_t)(-\log p^*(a|x_1 \cdots x_t)) - \sum_{a\in A} p(a|x_1 \cdots x_t)(-\log p(a|x_1 \cdots x_t))$$

$$= \sum_{a \in A} p(a|x_1 \cdots x_t) \log \frac{p(a|x_1 \cdots x_t)}{p^*(a|x_1 \cdots x_t)} \ .$$

So, we can see that from a mathematical point of view the prediction and adaptive coding are identical and can, therefore, be investigated together. Note that such a scheme of adaptive (or universal) coding was suggested in [3] and now is called as a PPM algorithm.

It is known that the redundancy of the Laplace predictor is upper bounded by $(|A| - 1)/(t + 1)$ [20, 21], if the predictor is applied to an i.i.d. source. Krichevsky [8, 9] investigated the problem of optimal minimax predictor for i.i.d. sources and showed that, loosely speaking, the redundancy of the optimal predictor is asymptotically equal to $(|A|-1)/(2t)+o(1/t)$. We can see that, on the one hand, the precision of the predictors essentially depends on the alphabet size $|A|$. On the other hand, there are many applications, where the alphabet size is unknown beforehand and can be upper bounded only. Moreover, quite often such a bound is infinity. That is why the problems of prediction and, especially, adaptive coding for large and infinite alphabet sources have been a subject in literature before, see [4, 14, 15, 11, 23].

In this paper we suggest a scheme of adaptive coding (and prediction) for a case where a source generates letters from an alphabet with unknown (and even infinite) size. This scheme can be applied along with Laplace, Krichevsky and any other predictors. If the suggested scheme is applied to $s-$ letter source and s is unknown, the redundancy is asymptotically the same as if the predictor is applied to the $(s + 1)-$ letter source and the alphabet size $(s + 1)$ is known beforehand.

When the suggested scheme is applied to an infinite alphabet, the redundancy of the code goes to 0, if, loosely speaking, the original representation of the alphabet letters has a finite average word length. It will be shown that, in fact, this condition is necessary for existing of such predictors.

We mainly consider a case of prediction for i.i.d. sources, because the predictors for i.i.d. sources are used as a "core" in the PPM scheme and other practically used adaptive codes and the performance of those codes effectively depends on the redundancy of the i.i.d. predictors. Besides, all results can be easily extended to Markov sources, using well known methods, see, for example., [8, 21].

2 Definitions and Preliminaries

Consider an alphabet $A = \{a_1, \cdots, a_n\}$ with $n \geq 2$ letters and denote by A^t the set of words $x_1 \cdots x_t$ of length t from A. Let p be a source which generates letters from A. Formally, p is a probability distribution on the set of words of infinite length or, more simply, $p = (p^t)_{t \geq 1}$ is a consistent set of probabilities over the sets A^t; $t \geq 1$. By $M_0(A)$ we denote the set of Bernoulli (or i.i.d.) sources over A.

Denote by $D(\cdot\|\cdot)$ the Kullback-Leibler divergence and consider a source p and a method γ of prediction. The *redundancy* is characterized by the divergence

$$r_{\gamma,p}(x_1 \cdots x_t) = D\left(p(\cdot|x_1 \cdots x_t)\|p^*_\gamma(\cdot|x_1 \cdots x_t)\right)$$

$$= \sum_{a \in A} p(a|x_1 \cdots x_t) \log \frac{p(a|x_1 \cdots x_t)}{p^*_\gamma(a|x_1 \cdots x_t)}. \tag{1}$$

(Here and below $\log \equiv \log_2$.)

For fixed t, $r_{\gamma,p}$ is a random variable, because $x_1, x_2, \cdots, x_t$ are random variables. We define the *average redundancy* at time t by

$$r^t(p\|\gamma) = E\ (r_{\gamma,p}(\cdot)) = \sum_{x_1 \cdots x_t \in A^t} p(x_1 \cdots x_t)\ r_{\gamma,p}(x_1 \cdots x_t). \tag{2}$$

Related to this quantity we define the *maximum average divergence* (at time t) by

$$r^t(M\|\gamma) = \sup_{p \in M} r^t(p\|\gamma), \tag{3}$$

where M is a set of sources. If the Laplace predictor

$$p^*_L(a|x_1 \cdots x_t) = (\nu^t(a) + 1)/(t + |A|) \tag{4}$$

is applied to i.i.d. source, its average redundancy ($r^t(p\|L)$) is upper bounded by $(|A| - 1) \log e/(t + 1)$, i.e.

$$r^t(M_0\|L) \leq (|A| - 1) \log e/(t + 1), \tag{5}$$

see [20, 21].(Here $e = 2.718...$ is the Euler number and, as before, $\nu^t(a)$ denote the count of letter a occurring in the word $x_1 \ldots x_{t-1}x_t$.) In [9] Krichevsky investigated the problem of optimal predictor for the set of i.i.d. sources and

showed that for any predictor π the maximal redundancy is asymptotically lower bounded by $(|A|-1)\log e/2t$:

$$\lim_{t\to\infty}\sup\left(2t\ r^t(M_0\|\pi)\right)\ \geq(|A|-1)\log e.$$

He has also suggested the predictor

$$p^*_{K_1}(a|x_1\cdots x_t)=(\nu^t(a)+\delta)/(t+\delta|A|), \tag{6}$$

where $\delta=0.50922...$, and shown that it is asymptotically optimal:

$$\lim_{t\to\infty}\sup\left(2t\ r^t(M_0\|K_1)\right)\ =(|A|-1)\log e. \tag{7}$$

As we mentioned above, predictors for i.i.d. sources can be easily extended to Markov sources (see, for example, [8, 21]) and to the general stationary and ergodic sources, as it was suggested in [18, 19]. But, it is worth noting that, as it is shown in [19], there exist such stationary and ergodic sources that their divergence does not go to 0. More precisely, for any predictor γ there exists such a stationary and ergodic source $\tilde{p}$, that $\lim_{t\to\infty}\sup\left(\ r^t(\tilde{p}\|\gamma)\right)\ \geq \log|A|$, (see [19, 1, 10]). But, on the other hand, it is shown in [18, 19] that there exists such a predictor ρ, that the following average $R^t(p\|\rho)=t^{-1}\sum_{i=1}^t r^i(p\|\rho)$ goes to 0 for any stationary and ergodic source p, where t goes to infinity. We will focus our attention on the per letter redundancy $r^t(\,\|\,))$, but all estimates can be easily extended to the $R^t(\,\|\,)$.

3 The new scheme

Let, as before, p be an i.i.d. source generating letters from the alphabet A. The probability distribution $p(a), a\in A$ is unknown and each letter x_{t+1} should be predicted (or encoded) using information on the word $x_1x_2\cdots x_t$ only.

The suggested scheme can be applied to any predictor (or letterwise coding), but we will use the Laplace predictor as the main example. We start the description of the new scheme using a simple example. Let $A=\{a_0,a_1,a_2,\}$ and $t=4$, $x_1x_2x_3x_4=a_0a_2a_0a_0$. The "common" Laplace predictor is as follows:

$$p^*_L(x_5=a_0)=(3+1)/(4+3)=4/7, p^*_L(x_5=a_1)=(0+1)/(4+3)=1/7,$$

$$p_L^*(x_5 = a_0 = (1+1)/(4+3) = 2/7,$$

see (4). In this example we suggest to group letters into two subsets $A_0 = \{a_0, a_1\}, A_1 = \{a_3\}$ and carry out the prediction into two steps. First, the original sequence $a_0a_2a_0a_0$ is represented as $A_0A_1A_0A_0$ and belonging to the subsets is predicted as follows

$$p_L^*(x_5 \in A_0) = (3+1)/(4+2) = 2/3, p_L^*(x_5 \in A_1) = (1+1)/(4+2) = 1/3.$$

We know that A_1 contains one letter (a_3), hence, $p_L^*(x_5 = a_3) = 1/3$. The sequence $A_0A_1A_0A_0$, which contains three letters A_0, is used for predicting conditional probabilities $p(x_5 = a_i/x_5 \in A_0)$, $i = 0, 1$. Again, we apply the Laplace predictor (4) to the sequence $A_0A_0A_0 = a_0a_0a_0$ and obtain the following prediction: $p(x_5 = a_0/x_5 \in A_0) = (3+1)/(3+2) = 4/5, p(x_5 = a_1/x_5 \in A_0)$
$= (0+1)/(3+2) = 1/5$. So, combining all predictions, we obtain $p_L^*(x_5 = a_0) = (2/3)(4/5) = 8/15$, $p_L^*(x_5 = a_1) = (2/3)(1/5) = 2/15$, $p_L^*(x_5 = a_0) = 1/3$. We can see that this prediction and the "common" one are different.

It will be convenient to describe the general case using the notation of a tree. Let Υ be a rooted tree, which contains $|A|$ leaves, and let each leaf be marked by one letter from A in such a way that different leaves are marked by different letters.

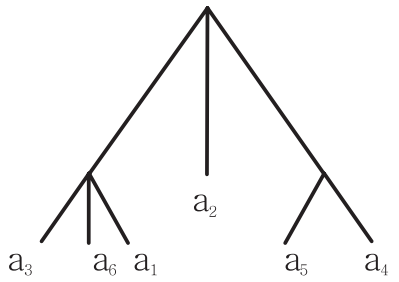

Figure 1: $A_{\alpha_1} = \{a_1, a_3, a_6\}, A_{\alpha_2} = \{a_2\}, A_{\alpha_3} = \{a_4, a_5\}, A_{\alpha_{1,1}} = \{a_3\}, \dots$.

We will mark each vertex $\mu \in \Upsilon$ by a subset of A_μ as follows. We consider the subtree Υ_μ whose root is the vertex μ and define the subset A_μ by the set of all letters, which mark the leaves of the subtree Υ_μ. Note that $\Upsilon_{root} = A$. We denote vertexes of the depth one by $\alpha_i, i = 1, ..., k$,

the vertexes of the depth 2 by $\alpha_{i,j}, j = 1, ..., k_i, i = 1, ..., k$, etc., where k is the number of the depth 1 vertexes, k_i is the number of the sons of the vertex i, etc. The prediction is carried out as follows. First a generated sequence $x_1 \dots x_t$ is represented as the sequence $A_{\alpha_{i_1}} A_{\alpha_{i_2}} \dots A_{\alpha_{i_t}}$, where α_{i_j} is such a vertex of the depth one, that the letter x_j belongs to the subset $A_{\alpha_{i_j}}$. Then, $A_{\alpha_{i_1}} A_{\alpha_{i_2}} \dots A_{\alpha_{i_t}}$ is considered as the sequence generated by an i.i.d. source with the alphabet $\{A_{\alpha_i}, i = 1, ..., k\}$ and the next letter $A_{\alpha_{i_{t+1}}}$ is predicted (say, by Laplace predictor). In fact, $p^*_L(A_{\alpha_i})$ is the estimation of $Pr\,(x_{t+1} \in A_{\alpha_i})$. Then, for each vertex $\alpha_{i,j}, i = 1, ..., k, j = 1, ..., k_i$ of the depth 2, which is not a leaf, we estimate the probability $Pr(x_{t+1} \in A_{\alpha_{i,j}}/x_{t+1} \in A_{\alpha_i})$. For this purpose for each i we consider all letters A_{α_i} in the sequence $A_{\alpha_{i_1}} A_{\alpha_{i_2}} \dots A_{\alpha_{i_t}}$ and organize the following sequence of their sons $A_{\alpha_{i,j_1}} ... A_{\alpha_{i,j_s}}$, whose length s equals the count of occurrences A_{α_i} in the sequence $A_{\alpha_{i_1}} A_{\alpha_{i_2}} \dots A_{\alpha_{i_t}}$. This sequence is considered as a generated by an i.i.d. source and the next letter $A_{\alpha_{i,j_s}}$ is predicted. As a result, we obtain $p^*_L(A_{\alpha_{i,j}})$, which are, in fact, the estimations of the probabilities $Pr(x_{t+1} \in A_{\alpha_{i,j}}/x_{t+1} \in A_{\alpha_i})$. And so on. Then we calculate the predictor $P^*_\Upsilon(x_{t+1} = a)$ as a product $Pr\,(x_{t+1} \in A_{\alpha_i})\ Pr(x_{t+1} \in A_{\alpha_{i,j}}/x_{t+1} \in A_{\alpha_i})\ Pr(x_{t+1} \in A_{\alpha_{i,j,m}}/x_{t+1} \in A_{\alpha_{i,j}})$ ..., where $a \in A_{\alpha_i}$, $a \in A_{\alpha_{i,j}}$, $a \in A_{\alpha_{i,j,m}}$, ...

The following example is to illustrate all steps. Let the alphabet A be $\{a_1, \dots, a_6\}$ and the tree Υ is shown on the figure 1. Let the generated sequence $x_1 \dots x_t$ be $a_3a_1a_5a_5a_2a_5a_4a_2a_3$. According to the tree Υ, firstly this sequence is represented as $A_{\alpha_1} A_{\alpha_1} A_{\alpha_3} A_{\alpha_3} A_{\alpha_2} A_{\alpha_3} A_{\alpha_3} A_{\alpha_2} A_{\alpha_1}$ and the next letter x_{t+1} is predicted as follows: $P^*_{L\Upsilon}(x_{t+1} \in A_{\alpha_1}) = (3+1)/(9+3)$, $P^*_{L\Upsilon}(x_{t+1} \in A_{\alpha_2}) = (2+1)/(9+3)$, $P^*_{L\Upsilon}(x_{t+1} \in A_{\alpha_3}) = (4+1)/(9+3)$. Then we divide the sequence of subsets $A_{\alpha_1} A_{\alpha_1} A_{\alpha_3} A_{\alpha_3} A_{\alpha_2} A_{\alpha_3} A_{\alpha_3}$
$A_{\alpha_2} A_{\alpha_1}$ into the three following subsequences $A_{\alpha_1} A_{\alpha_1} A_{\alpha_1}$, $A_{\alpha_2} A_{\alpha_2}$ and $A_{\alpha_3} A_{\alpha_3} A_{\alpha_3} A_{\alpha_3}$. The set A_{α_2} contains only one letter a_2, hence, the prediction of this letter coincides with the prediction of the subset A_{α_2}: $p^*_{L\Upsilon}(x_{t+1} = a_2) = P^*_{L\Upsilon}(x_{t+1} \in A_{\alpha_2}) = (2+1)/(9+3)$. The first subsequence $A_{\alpha_1} A_{\alpha_1} A_{\alpha_1}$ is represented as $a_3a_1a_3$ and the next letter is predicted by $P^*_{L\Upsilon}(x_{t+1} = a_1/x_{t+1} \in A_{\alpha_1}) = (1+1)/(3+3)$, $P^*_{L\Upsilon}(x_{t+1} = a_3/x_{t+1} \in A_{\alpha_1}) = (2+1)/(3+3)$, $P^*_{L\Upsilon}(x_{t+1} = a_6/x_{t+1} \in A_{\alpha_1}) = (0+1)/(3+3)$. The third subsequence $A_{\alpha_3} A_{\alpha_3} A_{\alpha_3} A_{\alpha_3}$ is represented as $a_5a_5a_5a_4$ and we obtain the following prediction: $P^*_{L\Upsilon}(x_{t+1} = a_4/x_{t+1} \in A_{\alpha_3}) = (1+1)/(4+2)$, $P^*_{L\Upsilon}(x_{t+1} = a_5/x_{t+1} \in A_{\alpha_3}) = (3+1)/(4+2)$. Finally, we obtain

$$P^*_{L\Upsilon}(x_{t+1} = a_1) = (4/12)(2/6), P^*_{L\Upsilon}(x_{t+1} = a_2) = (3/12),$$

$$P^*_{L_\Upsilon}(x_{t+1}=a_3)=(4/12)(3/6), P^*_{L_\Upsilon}(x_{t+1}=a_4)=(5/12)(2/6),$$
$$P^*_{L_\Upsilon}(x_{t+1}=a_5)=(5/12)(4/6), P^*_{L_\Upsilon}(x_{t+1}=a_6)=(4/12)(1/6).$$

The properties of the suggested scheme are as follows.

Theorem 1. Let $x_1 \dots x_t$ be a sequence generated by an i.i.d. source from an alphabet A. If the letter x_{t+1} is predicted by the suggested scheme according to a tree Υ with the set of vertex Λ , then the following upper bound for the precision (or redundancy) (2) is valid:

$$r^t(p\|L_\Upsilon) \le \log e \sum_{\lambda\in\Lambda} \min\{\,(\sigma(\lambda)-1)/(t+1),\ p(A_\lambda)\}\,, \qquad (8)$$

where $\sigma(\lambda)$ is the number of sons of the vertex λ, $p(A_\lambda)=\sum_{a\in A_\lambda} p(a)$, L_Υ is a notation of the predictor.

Proof is in Appendix.

Comment. The summands, which correspond to leaves in (8), are equal to 0, because $A_\lambda = 1$, if λ is a leaf. So, if we define the set of internal vertex by Λ_{int} we can rewrite (8) as follows:

$$r^t(p\|L_\Upsilon) \le \log e \sum_{\lambda\in\Lambda_{int}} \min\{\,(\sigma(\lambda)-1)/(t+1),\ p(A_\lambda)\}\ .$$

Corollary. The "common" Laplace predictor corresponds to the tree which consists of a root with $|A|$ sons (leaves). From Theorem 1 we immediately obtain the upper bound (5).

4 The unknown and infinite alphabet

Of course, the suggested scheme can be generalized in such a way that the tree Υ, which determines the algorithm of prediction, depends on the encoded part $x_1...x_t$. We consider one such scheme, which is close, in spirit, to some methods basing on the estimate of an escape probability [11, 23], and show how Theorem 1 can be used for obtaining an asymptotic estimations of the redundancy in the case where the algorithm of prediction (or the tree Υ) depends on the sequence.

In order to describe this predictor we define the subset A^t_0, which contains all 0-frequent letters at the moment t and let $A^t_+ = A - A^t_0$. The predictor η_t is defined as follows:

$$\eta^t(a) = \begin{cases} (\nu^t(a)+1)/(t+|A_+^t|+1), & \text{if } \nu^t(a) > 0; \\ 1/((t+|A_+^t|+1)\,|A_0^t|), & \text{if } \nu^t(a) = 0\ . \end{cases}$$

In words, the letter x_{t+1} is encoded according to the tree Υ_t, whose root has $|A_+^t|+1$ sons. Of these, $|A_+^t|$ are leaves corresponding to the letters from the set A_+^t (i.e. their frequencies are greater than 0). One son of the root corresponds to the set A_0^t and has $|A_0^t|$ sons, which, in turn, correspond to the letters from A_0^t. This code is close to some methods, which are based on estimate of the escape probability, see [23]. It is interesting that, asymptotically, the increase of the redundancy is the same as if the alphabet size would increase by one. In words, if the suggested scheme is applied to $s-$ letter source and s is unknown, the redundancy is the same as if the predictor is applied to $(s+1)-$ letter source and the alphabet size $(s+1)$ is known beforehand. More precisely, the following property is valid.

Theorem 2. Let the predictor η_t be applied to an i.i.d. source p with an alphabet A. Then, the following inequality is valid:

$$\limsup_{t\to\infty} (\ t\ r^t(p)\|\eta_t)\ ) \ \le\ \min\{s, |A|-1\},$$

where s is the number of the alphabet letters whose probability is not 0.

Proof is in Appendix.

Comment. The Krichevsky predictor (6) can be used along with the described scheme (instead of the Laplace predictor). If we define this predictor as $\tilde{\eta}_t$, then the following inequality is valid:

$$\limsup_{t\to\infty} (\ 2\,t\ r^t(p)\|\tilde{\eta}_t)\ ) \ \le\ \min\{s, |A|-1\}.$$

If we compare these inequalities with the redundancy of the common Laplace predictor (5) and the Krichevsky one (7), we can see that the "payment" for the lack of knowledge of the alphabet size is asymptotically as large as it could be caused increasing the alphabet by 1 letter. In words, if the letters with nonzero probabilities are known beforehand, the redundancy of the common Laplace predictor is $(s-1)/(t+1)$, where s is the number of letters with nonzero probabilities.

Now we consider the case of infinite alphabet $A = \{a_1, ..., a_n, ...\}$. We suppose that there is an i.i.d. source, which generates letters from A with a probability distribution p. Obviously, the first letter x_1 must be encoded by an encoder and decoded by a decoder based on an initial code (over

some finite alphabet), which is known to both the encoder and the decoder. (Otherwise, the first letter cannot be transmitted.) We denote this initial code by $c = \{c_1, c_2, ...\}$ and suppose that the letter a_i is encoded by the word c_i. Of course, we also suppose that the code c is uniquely decodable. Moreover, we will suppose that c is the prefix code, because it is known that for each decodable code c there exists such a prefix code c^* that their codeword lengths are equal ($|c_i| = |c_i^*|$ for all i), see [6].

If one wants to use this code for encoding and decoding the first letter x_1, the average codeword length of this letter should be finite, i.e.

$$E_p(c_i) \equiv \sum_{i=1}^{\infty} p(a_i)\,|c_i| < \infty\,. \tag{9}$$

For example, if the (binary) code and the probability distribution are as follows:

$$c_1 = 0, c_2 = 10, c_3 = 110, c_4 = 1110, ...; p(a_1) = 1/2, p(a_2) = 1/4, p(a_3) = 1/8, ...,$$

then the average codeword length $E_p(|c_i|) = 2$ bits and, hence, such a code can be used for a coding x_1. On the other hand, consider the same probability distribution and a new code $\bar{c}$ such that $|\bar{c}_i| = 2^i$. This code cannot be used, because its average codeword length is infinite and the first letter x_1 cannot be transmitted from an encoder to an decoder. So, our requirement is as follows: We do not know the source probabilities, but know a code c, whose average codeword length is finite. The following theorem shows that this requirement is sufficient for existing such an adaptive code, whose redundancy goes to 0. In a certain sense this requirement is necessary, because nobody can transmit the first letter of the generated sequence, if he/she does not know such a code.

Theorem 3. Suppose that there are a source generated letters from an infinite alphabet A with (unknown) distribution p and a prefix code $c(a), a \in A$ over some finite alphabet such that the average length $E_p(|c(a)|)$ is finite. Denote by Γ the tree which corresponds to the code c and let L_Γ be the Laplace predictor corresponding to the tree Γ. Then the redundancy of this method goes to 0:

$$\lim_{t\to\infty} r^t(p\|L_\Gamma) = 0.$$

Proof is in Appendix.

Corollary. If the source alphabet A is infinite, but it is known that only a finite number of letters have nonzero probabilities, the average codeword length (9) is finite for any code and, hence, Theorem 3 is valid for any prefix code.

5 Appendix

The proof of the theorem 1. We will use two following lemmas.

Lemma 1. Let a Bernoulli source generate t letters from the alphabet $A^* = \{A, \bar{A}\}$ with probabilities $p(A)$ and $p(\bar{A})$ and let $\vartheta(A)$ be a count of occurrence of the letter A in the generated sequence. Then the following inequality is valid:

$$p(A)\ E_p(\ 1/(\vartheta(A)+1) \le \min\{p(A),\ 1/(t+1)\ \},$$

where E_p is an expectation.

Proof of the lemma 1. The inequality $p(A)\ E_\vartheta(\ 1/(\vartheta(A)+1) \le p(A)$ is followed from the obvious inequality $E_p(\ 1/(\vartheta(A)+1) \le E_\vartheta(\ 1) = 1$.

The second inequality $p(A)\ E_\vartheta(\ 1/(\vartheta(A)+1) \le\ 1/(t+1)$ is proved as follows:

$$p(A)\ E_\vartheta(\ 1/(\vartheta(A)+1) = p(A)\ \sum_{j=0}^{t}(\ \begin{matrix} t \\ j \end{matrix}\ )p(A)^j(1-p(A))^{t+1-j}\ )$$

$$\le \frac{1}{t+1}\sum_{s=0}^{t+1}(\ \begin{matrix} t+1 \\ s \end{matrix}\ )p(A)^s(1-p(A))^{t+1-s}\ ) = \frac{1}{t+1}.$$

The lemma is proven.

Lemma 2. Let a Bernoulli source generate t letters from the finite alphabet $A = \{a\}$ with probabilities $p(a), a \in A$. Then the redundancy of the "common" Laplace predictor (4) can be upper bounded by $\log e\frac{|A|-1}{t+1}$. (Though Lemma 2 is known for the Laplace predictor ([20, 21]) we give the details of the proof for the convenience of the reader.)

We employ the general inequality

$$D(\mu\|\eta) \le \log e\ (-1 + \sum_{a\in A}\mu(a)^2/\eta(a)),$$

valid for any distributions μ and η over A (follows from the elementary inequality $\ln x \le x-1$) From the definition of the redundancy (or precision) (1), (2) and (4) we obtain

$$r^t(p\|L) = E_{p^t}D(p(\cdot\mid x_1\cdots x_t)\|p^*(\cdot\mid x_1\cdots x_t))$$

$$= E_{p^t}(D(p\|p^*_L(\cdot\mid x_1\cdots x_t)) \le \log e\ (-1 + \sum_{x_1\cdots x_t\in A^t} p(x_1\cdots x_t)$$

$$\sum_{a\in A}\frac{p(a)^2(t+|A|)}{\nu_a(x_1\cdots x_t)+1}\,) = \log e(-1+\sum_{a\in A}\sum_{i=0}^{t}\frac{p(a)^2(t+|A|)}{i+1}$$

$$((\ {t\atop i}\ )p(a)^i(1-p(a))^{t-i})) = \log e(-1+\frac{t+|A|}{t+1}\sum_{a\in A}p(a)$$

$$\sum_{i=0}^{t}(\ {t+1\atop i+1}\ )p(a)^{i+1}(1-p(a))^{t-i}\,) \le \log e(-1+\frac{t+|A|}{t+1}\sum_{a\in A}p(a)$$

$$\sum_{j=0}^{t+1}(\ {t+1\atop j}\ )p(a)^{j}(1-p(a))^{t+1-j}\,) = \log e\,\frac{|A|-1}{t+1}.$$

The lemma is proven.

Consider a letter $a\in A$ and let α_{i_1}, α_{i_1,i_2}, $\ldots$, $\alpha_{i_1,i_2,\ldots,i_s}$ be a sequence of vertexes such that

$$A_{\alpha_{i_1}}\supset A_{\alpha_{i_1,i_2}}\ldots\supset A_{\alpha_{i_1,i_2,\ldots,i_s}}$$

and $A_{\alpha_{i_1,i_2,\ldots,i_s}}=\{a\}$. The estimation of the probability (or prediction) $p(x_{t+1}=a)$ can be represented as follows

$$p^*_{L_\Upsilon}(a)=\Big((\nu^t(A_{\alpha_{i_1}})+1)/(t+\sigma(root))\Big)\ \ \Big((\nu^t(A_{\alpha_{i_1,i_2}})+1)/(\nu^t(A_{\alpha_{i_1}})+\sigma(\alpha_{i_1}))\Big)$$

$$(\nu^t(A_{\alpha_{i_1,i_2,i_3}})+1)/(\nu^t(A_{\alpha_{i_1,i_2}})+\sigma(\alpha_{i_1,i_2}))\ \ldots(\nu^t(A_{\alpha_{i_1,\ldots,i_s}})+1)/(\nu^t(A_{\alpha_{i_1,\ldots,i_{s-1}}})+\sigma(\alpha_{i_1,\ldots,i_{s-1}})),$$

where $\nu^t(A_\alpha)$ is a number of occurrences of letters from the subset A_α in the sequence $x_1\ldots x_t$. From this equality and the definition of the redundancy we obtain the following equality:

$$r^t(p|L_\Upsilon)=E_{p(x_1\ldots x_t)}(\sum_{a\in A}p(a)\log(p(a)/p^*_{L_\Upsilon}(a))=\sum_{a\in A}p(a)$$

$$\{\ \log\frac{p(A_{\alpha_{i_1}})}{((\nu^t(A_{\alpha_{i_1}})+1)/(t+\sigma(root)}$$

$$+\ \log\frac{(p(A_{\alpha_{i_1,i_2}})/p(A_{\alpha_{i_1}}))}{(\nu^t(A_{\alpha_{i_1,i_2}})+1)/(\nu^t(A_{\alpha_{i_1}})+\sigma(\alpha_{i_1}))}$$

$$+\ \log\frac{(p(A_{\alpha_{i_1,i_2,i_3}})/p(A_{\alpha_{i_1,i_2}}))}{((\nu^t(A_{\alpha_{i_1,i_2,i_3}})+1)/(\nu^t(A_{\alpha_{i_1,i_2}}+\sigma(\alpha_{i_1,i_2})))}\ \ldots$$

$$+\ \log\frac{(p(A_{\alpha_{i_1,\ldots,i_s}})/p(A_{\alpha_{i_1,\ldots,i_{s-1}}}))}{((\nu^t(A_{\alpha_{i_1,\ldots,i_s}})+1)/(\nu^t(A_{\alpha_{i_1,\ldots,i_{s-1}}})+\sigma(\alpha_{i_1,\ldots,i_{s-1}})))}\ \}\ ).$$

Grouping summands, we obtain

$$r^t(p|L_\Upsilon) = E(\ \sum_{i_1} p(A_{\alpha_{i_1}})\ \log \frac{p(A_{\alpha_{i_1}})}{(\nu^t(A_{\alpha_{i_1}})+1)/(t+\sigma(root))})$$

$$+\sum_{i_1} p(A_{\alpha_{i_1}}) E(\sum_{i_2} \frac{p(A_{\alpha_{i_1,i_2}})}{p(A_{\alpha_{i_1}})} \log \frac{p(A_{\alpha_{i_1,i_2}})/p(A_{\alpha_{i_1}})}{((\nu^t(A_{\alpha_{i_1,i_2}})+1)/(\nu^t(A_{\alpha_{i_1}})+\sigma(\alpha_{i_1})}))+\ ...$$

$$+\sum_{i_1} p(A_{\alpha_{i_1}}) \sum_{i_2} \frac{p(A_{\alpha_{i_1,i_2}})}{p(A_{\alpha_{i_1}})} ... E(\sum_{i_s} \frac{p(A_{\alpha_{i_1,\ldots,i_s}})}{p(A_{\alpha_{i_1,\ldots,i_{s-1}}})}$$

$$\log \frac{p(A_{\alpha_{i_1,\ldots,i_s}})/p(A_{\alpha_{i_1,\ldots,i_{s-1}}})}{(\nu^t(A_{\alpha_{i_1,\ldots,i_s}})+1)/(\nu^t(A_{\alpha_{i_1,\ldots,i_{s-1}}})+\sigma(\alpha_{i_1,\ldots,i_{s-1}})}))+...,$$

where $E(\ )$ means an expectation. It is worth noting that such a grouping is correct for the case of infinite A, because all values $E(\ )$ are nonnegative.

Having taken into account this equality and Lemma 2 we can upper bound the redundancy as follows:

$$r^t(p|L_\Upsilon) \le \log e\ \{\ (\sigma(root)-1)/(t+1))$$

$$+E\,(\sum_{i_1} p(A_{\alpha_{i_1}}) \frac{\sigma(\alpha_{i_1})-1}{(\nu^t(A_{\alpha_{i_1}})+1)}) +\ ...$$

$$+\sum_{i_1} p(A_{\alpha_{i_1}}) \sum_{i_2} \frac{p(A_{\alpha_{i_1,i_2}})}{p(A_{\alpha_{i_1}})} ... E\,(\sum_{i_{s-1}} \frac{p(A_{\alpha_{i_1,\ldots,i_{s-1}}})}{p(A_{\alpha_{i_1,\ldots,i_{s-2}}})}$$

$$\frac{\sigma(\alpha_{i_1,\ldots,i_{s-1}})-1}{(\nu^t(A_{\alpha_{i_1,\ldots,i_{s-1}}})+1)}\ +...\}.$$

Let us estimate one summand, say,

$$\sum_{i_1} p(A_{\alpha_{i_1}}) \sum_{i_2} \frac{p(A_{\alpha_{i_1,i_2}})}{p(A_{\alpha_{i_1}})} \sum_{i_3} E(\frac{p(A_{\alpha_{i_1,i_2,i_3}})}{p(A_{\alpha_{i_1,i_2}})} \frac{\sigma(\alpha_{i_1,i_2,i_3})-1}{(\nu^t(A_{\alpha_{i_1,i_2,i_3}})+1)}.$$

(General case is obvious). From Lemma 1 we obtain the following inequalities

$$\sum_{i_1} p(A_{\alpha_{i_1}}) \sum_{i_2} \frac{p(A_{\alpha_{i_1,i_2}})}{p(A_{\alpha_{i_1}})} E\,(\sum_{i_3} \frac{p(A_{\alpha_{i_1,i_2,i_3}})}{p(A_{\alpha_{i_1,i_2}})} \frac{\sigma(\alpha_{i_1,i_2,i_3})-1}{(\nu^t(A_{\alpha_{i_1,i_2,i_3}})+1)})$$

$$= \sum_{i_1} p(A_{\alpha_{i_1}}) \sum_{i_2} \frac{p(A_{\alpha_{i_1,i_2}})}{p(A_{\alpha_{i_1}})} \sum_{i_3} (\sigma(\alpha_{i_1,i_2,i_3})-1) E\,(\frac{p(A_{\alpha_{i_1,i_2,i_3}})}{p(A_{\alpha_{i_1,i_2}})} \frac{1}{(\nu^t(A_{\alpha_{i_1,i_2,i_3}})+1)})$$

$$\leq \sum_{i_1} p(A_{\alpha_{i_1}}) \sum_{i_2} \frac{p(A_{\alpha_{i_1,i_2}})}{p(A_{\alpha_{i_1}})} \sum_{i_3} (\sigma(\alpha_{i_1,i_2,i_3})-1) E \min\{\frac{p(A_{\alpha_{i_1,i_2,i_3}})}{p(A_{\alpha_{i_1,i_2}})}, \frac{1}{(\nu^t(A_{\alpha_{i_1,i_2}})+1)}\}$$

$$= \sum_{i_1} p(A_{\alpha_{i_1}}) \sum_{i_2} \sum_{i_3} (\sigma(\alpha_{i_1,i_2,i_3}) - 1) \min\{\frac{p(A_{\alpha_{i_1,i_2,i_3}})}{p(A_{\alpha_{i_1}})}, E(\frac{p(A_{\alpha_{i_1,i_2}})/p(A_{\alpha_{i_1}})}{(\nu^t(A_{\alpha_{i_1,i_2}})+1)})\}$$

$$\leq \sum_{i_1} p(A_{\alpha_{i_1}}) \sum_{i_2} \sum_{i_3} (\sigma(\alpha_{i_1,i_2,i_3}) - 1) \min\{\frac{p(A_{\alpha_{i_1,i_2,i_3}})}{p(A_{\alpha_{i_1}})}, E(\frac{1}{(\nu^t(A_{\alpha_{i_1}})+1)})\}$$

$$= \sum_{i_1} \sum_{i_2} \sum_{i_3} (\sigma(\alpha_{i_1,i_2,i_3}) - 1) \min\{p(A_{\alpha_{i_1,i_2,i_3}}), E(\frac{p(A_{\alpha_{i_1}})}{(\nu^t(A_{\alpha_{i_1}})+1)})\}$$

$$\leq \sum_{i_1} \sum_{i_2} \sum_{i_3} (\sigma(\alpha_{i_1,i_2,i_3}) - 1) \min\{p(A_{\alpha_{i_1,i_2,i_3}}), \frac{1}{(t+1)}\}.$$

From this estimation and the last upper bound for $r^t(p|L_\Upsilon)$ we obtain the inequality

$$r^t(p|L_\Upsilon) \leq \log e\ \{\ (\sigma(root)-1)/(t+1)) + \sum_{i_1} (\sigma(\alpha_{i_1})-1) \min\{p(A_{\alpha_{i_1}}), \frac{1}{(t+1)}\}$$

$$+ \sum_{i_1} \sum_{i_2} (\sigma(\alpha_{i_1,i_2}) - 1) \min\{p(A_{\alpha_{i_1,i_2}}), \frac{1}{(t+1)}\}$$

$$+ \sum_{i_1} \sum_{i_2} \sum_{i_3} (\sigma(\alpha_{i_1,i_2,i_3}) - 1) \min\{p(A_{\alpha_{i_1,i_2,i_3}}), \frac{1}{(t+1)}\} + ...\}.$$

In fact, the last inequality is (8) and Theorem 1 is proven.

The proof of the theorem 3. Let $\varepsilon > 0$ be some number. There exists such a finite subset $A_\varepsilon \subset A$ that

$$\sum_{a \in (A - A_\varepsilon)} p(a)|C(a)| < \varepsilon/(2 \log e), \tag{10}$$

because the sum $\sum_{a\in A} p(a)|C(a)|$ is finite. The redundancy of the code L_Γ can be represented as two following summands:

$$r^t(p\|L_\Gamma) = \sum_{a\in A_\varepsilon} p(a)\log(p(a)/p^*_{L^t_\Gamma}(a)) + \sum_{a\in(A-A_\varepsilon)} p(a)\log(p(a)/p^*_{L^t_\Gamma}(a)), \quad (11)$$

where L^t_Γ is the Laplace probability assignment at the moment t. The number of vertex in the subtree corresponding to A_ε is finite. Hence, if we apply the theorem 1, we obtain the following upper bound for the first summand in (11):

$$\sum_{a\in A_\varepsilon} p(a)\log(p(a)/p^*_{L^t_\Gamma}(a)) \le const/(t+1).$$

Hence, there exists such t_0 that the first summand in (11) is less than $\varepsilon/2$, if $t > t_0$. Let us estimate the second summand in (11). First we define the subset Λ_ε, which contains all vertex belonged to passes from the root to each letter from $A - A_\varepsilon$. Applying the theorem 1, we obtain

$$\sum_{a\in(A-A_\varepsilon)} p(a)\log(p(a)/p^*_{L^t_\Gamma}(a)) \le \log e \sum_{\lambda\in\Lambda_\varepsilon} p(A_\lambda) = \log e \sum_{\lambda\in\Lambda_\varepsilon}\Big(\sum_{a\in A_\lambda} p(a)\Big).$$

If we define the number of vertex belonged to the passe from the root to the leaf a as $\chi(a)$ we can rewrite the latest inequality as follows.

$$\sum_{a\in(A-A_\varepsilon)} p(a)\log(p(a)/p^*_{L^t_\Gamma}(a)) \le \log e \sum_{a\in A_\varepsilon} p(a)\chi(a).$$

By definition the codeword length $|C(a)|$ of any letter a is equal to $\chi(a)$. Hence, having taken into account this fact, from the latest inequality and (10) we obtain the following upper bound for the second summand:

$$\sum_{a\in(A-A_\varepsilon)} p(a)\log(p(a)/p^*_{L^t_\Gamma}(a)) \le \varepsilon/2.$$

So, each summands in (10) is upper bounded by $\varepsilon/2$ and it is true for any positive ε. Theorem 2 is proven.
